Irrational Exuberance: Why we should not believe 95% of papers on Time Series Anomaly Detection

Eamonn Keogh

Distinguished Professor University of California Riverside

UCR

Overarching Claim

- About 95% of papers on Time Series Anomaly Detection (TSAD) have one or more flaws. These flaws include:
 - Testing on deeply flawed datasets
 - Trivial
 - Mislabeled
 - Unrealistic Anomaly Density
 - Run-to failure
 - Use of inappropriate measures of success
 - Non-reproducible experiments
 - Assuming Deep Learning is the answer and ignoring competitive decade-year-old methods
 - Stabbing William of Ockham in the Heart unjustified complexity
 - Not doing anomaly detection, but then calling it anomaly detection.
- Because of these flaws, I argue that their contributions are nil.

Testing on deeply flawed datasets

 Some papers only test on private datasets or synthetic data², I will ignore these, as we all should!

 The vast majority of TSAD papers¹ use one or more of datasets created by Yahoo, Numenta, SMAP (NASA), MSL (NASA), SDM ("OMNI" Pei's Lab), MBA-ECG (Boniol) or SWAT.

• Let us take the time to look at these benchmark datasets.

¹Wu and Keogh: **Current Time Series Anomaly Detection Benchmarks are Flawed and are Creating the Illusion of Progress.** ²I do see a *limited* role for some experiments on synthetic data in *some* cases

The Benchmarks are often Mislabeled: Part I

July 1st (2014)

Consider the famous New York Taxi example from Numenta. This is one of the most common benchmarks. It is claimed that there are *five* anomalies: NYC marathon, Thanksgiving, Christmas, New Year's day, and a Blizzard.

New York Taxi Demand

Jan 31st (2015)

The Benchmarks are often Mislabeled: Part I

Consider the famous New York Taxi example from Numenta. This is one of the most common benchmarks It is claimed that there are *five* anomalies: NYC marathon, Thanksgiving, Christmas, New Year's day, and a Bizzard However, I would argue that there are *at least* five or six additional anomalies, including additional holidays and protests. Moreover, the anomaly called *Marathon* is really the daylight savings clock change from the night before.

¹Len Feremans, et al. Pattern-Based Anomaly Detection in Mixed-Type Time Series. ECML/PKDD (1) 2019: 240-256

The Benchmarks are often Mislabeled: Part I

Consider the famous New York Taxi example from Numenta. This is one of the most common benchmarks It is claimed that there are *five* anomalies: NYC marathon, Thanksgiving, Christmas, New Year's day, and a Blizzard. However, I would argue that there are at least five or six additional anomalies, including additional holidays and protests. Moreover, the anomaly called *Marathon* is really the daylight savings clock change from the night before.

Knowing this, what do you think of a claim such as this, from a recent paper¹: "On the NY Taxi dataset FPOF got 0.877, but we got 0.879, showing our method is better"?

¹Len Feremans, et al. Pattern-Based Anomaly Detection in Mixed-Type Time Series. ECML/PKDD (1) 2019: 240-256

Once you realize that the claim of five anomalies in NY Taxi is nonsense. You begin to see many published claims as strange...

"The performance of Tri-CAD is compared with those of related methods, such as STL, SARIMA, LSTM, LSTM with STL, and ADSaS. The comparison results show that Tri-CAD outperforms the others in terms of the precision, recall, and F1 –score"

The perfect precision, recall and F1-scores claimed here, just happens to agree with significant mislabeling.

This strongly suggests overfitting

Time Series	Class	Fixed Window Size (<i>fws</i>)	Metrics	STL only	SARIMA only	LSTM only	LSTM with STL	Proposed Framework Tri-CAD
NAB			Precision	0.533	0.000	0.176	0.161	1.000
NYC	Class 1	206	Recall	0.889	0.000	0.333	1.000	1.000
Taxi			F_1 -score	0.667	0.000	0.231	0.277	1.000

Table 1. Comparisons of the proposed framework Tri-CAD and related met

The Benchmarks are often Mislabeled: Part IIa

400

In this Yahoo dataset, C is an anomaly...

The Benchmarks are often Mislabeled: Part IIb

In this Yahoo dataset, C is an anomaly, but D is not, yet they are *virtually identical* dropouts.

The Benchmarks are often Mislabeled: Part III

In this Yahoo dataset it is claimed A is an anomaly, but B is not

But literally nothing has changed between the two points

Mislabeling really matters!

This paper claims it outperforms all rivals on MSL dataset^[a]. But the margin of victory over three of its rivals is less than 3%.

However, the amount of mislabeling in this dataset an order of magnitude greater than that!

Here is an example from MSR: G-1. The only anomaly labeled in 4770 to 4890. However surely 4270 to 4285 and 6880 to 6894 are anomalies too. "USAD outperforms all methods on MSL.." [a]

Methods	MSL						
	Р	R	F1	F1*			
AE	0.8535	0.9748	0.8792	0.9101			
IF	0.5681	0.6740	0.5984	0.6166			
LSTM-VAE	0.8599	0.9756	0.8537	0.9141			
DAGMM	0.7562	0.9803	0.8112	0.8537			
OmniAnomaly	0.9140	0.8891	0.8952	0.9014			
USAD	0.8810	0.9786	0.9109	0.9272			

I have tried and tried to tell folks that if the underlying uncertainty in your labels is larger than any change in relative performance, the change is meaningless

Vijayant K. VP of Product: ML & AI at Optum

^[a] USAD : UnSupervised Anomaly Detection on Multivariate Time Series

My claim of mislabeled data is almost tautological

In fact, perfect ground truth labels are **impossible** for anomaly detection!

 (however, it *really* is the case that most of the benchmark datasets have mislabelings. In some cases, I was able to confirm with the datasets creators that they had made errors)

Ground Truth Labels are Impossible for Anomaly Detection!

- For some ML problems, we *can* get perfect ground truth, i.e., cats vs dogs
- However, for anomaly detection, we can *never* have perfect ground truth.
- Consider the example below, the electrical power demand for a factory...

• Many people have labeled a Friday holiday as an anomaly, that seems reasonable, right?

Ground Truth Labels are Impossible for Anomaly Detection!

- For some ML problems, we *can* get perfect ground truth, i.e., cats vs dogs
- However, for anomaly detection, we can *never* have perfect ground truth.
- Consider the example below, the electrical power demand for a factory...

- Many people have labeled a Friday holiday as an anomaly, that seems reasonable, right?
 - However, Joe says "No! The anomaly is at 5817, when the flood forced us to turn on the emergency pump"
 - And Sue says "No! The anomaly is the noise at 4900 to 5100, when we switch from gas to TIG welding"
 - But Tim says "No! The anomaly is at 5890, when daylight saving time made a day look longer"
 - And Bic says "No! The anomaly is at 7420 when we turned off the night lights for an hour as part of IDA"
- My point is, we *can* never know all the out-of-band possible causes for anomalies. We can never be sure that the anomaly we see, based on a priori or post-hoc information, is the only or "best" anomaly.

Implication: It is nonsense for anomaly detection papers to publish experimental results with four or five significant digits, when there is always large subjectively and uncertainty as to the ground truth.

The Benchmarks are often Trivial:

- A huge fraction of benchmark datasets are trivial to solve.
- To make that claim more concrete, I will define *trivial*.
 - A time series anomaly detection problem is *trivial* if it can be solved with a single line of standard library MATLAB code (or Python, R etc.)
 - We cannot "cheat" by calling a high-level built-in function such as *kmeans* or *ClassificationKNN* or calling custom written functions.
 - We must limit ourselves to basic vectorized primitive operations, such as *mean*, *max*, *std*, *diff*, etc.
- We may allow a single magic number in our one-liner. But recall that many anomaly detection algorithms have up to a dozen parameters, and at least a few seem "magic" to me.

The Benchmarks are often Trivial: Part I

From the OMNI Benchmark, used in dozens of top tier papers. A test dataset, with ground truth, how hard is this to solve?

0

The Benchmarks are often Trivial: Part I

From the OMNI Benchmark.

A test dataset, and three different one-liners that perfectly solve it.

The Benchmarks are often Trivial: Part II

From the Numenta Benchmark.

A test dataset, and a one-liner that perfectly solves it.

The Benchmarks are often Trivial: Part III

From the Yahoo Benchmark.

A test dataset, and a one-liner that perfectly solves it.

The Benchmarks are often Trivial: Part III

From the Yahoo Benchmark.

- A test dataset, and a one-liner that perfectly solves it.
- Note how exactly the one-liner predicts the ground truth labels

From the NASA MSL dataset.

A test dataset with three anomalies..

A complex method finds the three anomalies, plus one false positive.

However, a one liner can finds just the three anomalies correctly

Figure 5: The result of MRONet-FT on channel F-7 from the MSL data. The top row shows the actual anomaly locations and the bottom row shows the detected anomaly sequences, including a false positive.

Abstrac by detection in telemetry channels is a high pricraft, especially when considering the harsh d the magnitude of launch and op domain ext-

The Benchmarks are often Trivial: Part IIII

From the OMNI Benchmark.

This dataset has lots of anomalies, it has 38 dimensions and comes with training data.

The Benchmarks are often Trivial: Part IIII

From the OMNI Benchmark.

This dataset has lots of anomalies, it has 38 dimensions and comes with training data.

But here, a single line of code, and a single dimension, no training data, no parameters, we can do almost perfectly, and better than any published result. This single line of code is basic **statistical process control**, about 80 years old.

T > mean(T) + (2* std(T));

Not convinced by one-liner argument?

Let's look at one of the Yahoo Benchmarks, and compare it to a 20-year old simple method called *time series discords*.

(Time series discords can be computed by the Matrix Profile, or faster O(n) algorithms) Time Series Discords are:

- Fast to compute
- Simple to implement: 10 lines of code, a little more to compute fast.
- Require only a single parameter: A recent paper removed even that parameter. See MERLIN
- Do not need training data (but can use it if needed)

Time Series Discords do extremely well on all the benchmark datasets.

E. Keogh, J. Lin and A. Fu (2005). HOT SAX: Efficiently Finding the Most Unusual Time Series Subsequence. (ICDM 2005)

Philosophically: What does the one-liner argument mean?

The one-liner argument could be cast in more rigorous terms, perhaps arguing about linear separability or Kolmogorov complexity. However, that seems to be pretentious and unneeded.

Imagine the following problems

- Determine if an audio signal contains Brazilian or European Portuguese
- Determine if a text review of a product is positive or negative
- Segmentation of an arbitrary song into *intro*, *verse*, *chorus*, *bridge*, and *outro*

All these problems are solvable with ML.

Philosophically: What does the one-liner argument mean?

The one-liner argument could be cast in more rigorous terms, perhaps arguing about linear separability or Kolmogorov complexity. However, that seems to be pretentious and unneeded.

Imagine the following problems

- Determine if an audio signal contains Brazilian or European Portuguese
- Determine if a text review of a product is positive or negative
- Segmentation of an arbitrary song into *intro*, *verse*, *chorus*, *bridge*, and *outro*

All these problems are solvable with ML.

However, wouldn't you be suspicious if I could solve one of these with a single line of code?

You might investigate and perhaps say: *Ah yes, you could separate positive and negative reviews in that dataset, but only because positive reviews are in all uppercase, and negative reviews are in all lower case. Your success here says nothing about the general problem.*

This is what the one liner argument is saying. If I can solve a problem with five seconds of thought and one line of code, then surely the task has some trivial structure that makes it too easy to be interesting.

The Benchmarks are often Trivial: Summary

At least 90% of the benchmark datasets can be solved with very simple methods dating back decades, or with "one-liners".

At least 90% of the benchmark datasets can be solved without needing to even look at the training data!

This should be worrisome. In what sense do we need machine *learning*, or deep *learning*, when it is not clear we need to *learn* from the training data in any way?

E.S. Page, "On Problems in which a Change in a Parameter Occurs at an Unknown Point," Biometrika, vol. 44, no. 1-2, 1957, pp. 248-252.

The Benchmarks have other Problems: Run to failure bias

 (esp. Yahoo and NASA) Run to failure bias: Most of the anomalies appear at the end of a time series.

This means just guessing "near the end" does quite well.

Most anomalies are near the end

The Benchmarks have other Problems: Unrealistic Anomaly Density I

- Consider these examples from NASA MSL
- More that half the data is labeled as being an anomaly!
- "anomaly" is a synonym for "rarity", but these anomalies sure aren't rare.
- A real anomaly detection algorithm must be able to deal with the tiny prior probability of seeing an anomaly.
- As an aside, note that we also have both run-to-failure bias and triviality, and probably partial mislabeling

The Benchmarks have other Problems: Unrealistic Anomaly Density II

- Consider this dataset. It has 133 "anomalies", all of which are basically identical arrythmias. In my view...
 - Isn't this much closer to a classification or clustering problem?
 - If you find one anomaly, you are going to find them all. Reporting *we got 133 out of 133!* implies an unwarranted level of utility and success.
 - Even better, I would *try* to get one wrong, so I could report: *Our accuracy is 0.9924!*
 - Note that it is also trivial in the *one line of code* sense

The Benchmarks have other Problems: Unrealistic Anomaly Density III

In the real world, anomalies are rare...

One anomaly a year, not good. Two anomalies in a year, people start talking. Three anomalies in a year, better start looking for a new job

Mike Noskov, Director, Data Science, Aspen Technology

Spurious Precision is Rampant in TSAD I

- Many papers report three, four or five digits of precision for their experimental results.
- Of course, the great uncertainly in ground truth labels suggests that this is meaningless.

Spurious Precision is Rampant in TSAD I

- Many papers report three, four or five digits of precision for their experimental results.
- Of course, the great uncertainly in ground truth labels suggests that this is meaningless.
- However, even if we assumed that we had perfect ground truth labels, much of the precision claimed would *still* be wrong.
- Consider the below, this once-a-hour sampled sensor was broken from midnight to midnight on Xmas day.

- Suppose my algorithm finds this, can I claim that I got 24 out of 24?
- No!, these are not independent events, I got 1 out of 1, not 24 out of 24!
- Is this obvious to you? Great, but see the next two slides, and see many TSAD papers.

Spurious Precision is Rampant in TSAD I

- Consider this very trivial anomaly detection dataset, *ECG(A)* (it is shown in is entirety!!).
- A recent paper published an experiment on this dataset, giving results with 4 significant digits!
- This implies ludicrously fine distinctions are being made. However, I argue the results should be binary (*detected* | *not-detected*).
- If the precision relates to timing, then it is making a distinction down to 1/250th of a second, something that is medically impossible. (Quote from Cardiologist Dr. Greg Mason "No one could meaningfully label the onset with a precision greater than 1/10th of a second")
- Many TSAD papers make similarly meaninglessly overspecified claims, giving the illusion of careful and statistically meaningful distinctions being made. This is just nonsense.

ECG(A) or chfdbchf01275

Table 3:	Effectiveness	of	coarse-to-fine	fusion	in	the	pro-
posed RA	AMED model.						

ECG(A)	AUROC	AUPRC	F1
w/o coarse-to-fine fusion	0.6479	0.5035	0.4965
full model	0.7358	0.5714	0.5427

[a] Lifeng Shen, Zhongzhong Yu, Qianli Ma, James T. Kwok: Time Series Anomaly Detection with Multiresolution Ensemble Decoding. AAAI 2021: 9567-9575

Non-reproducible Experiments and Spurious Precision

- There are many papers that publish on *time series* that are publicly available, but the anomaly *labels* are not available!
- But if the anomaly *labels* are not available, then you cannot reproduce a single number.
- Moreover, this practice is open to an obvious idea for abuse: ¹Run your algorithm, then use *its* predictions as the ground truth!

¹I am not claiming the paper on this page did that, but I do think papers have done this

Neurips 2020

Table 2: Precision (prec), recall (rec) and F1 score results (as %) on various data sets. The number in brackets after the F1 value is the rank of the method. The smaller the better

THOC	54.78	75.00	63.31 (1)	61.50	36.34	45.68 (1)		

Non-reproducible Experiments and Spurious Precision

- In this case, I happen to have introduced both 2D-guesture and power-demand to the community almost 20 years ago.
- These are reasonable datasets for showing anecdotal examples.
- But the anomalies within them are highly subjective, there is simply no way to pull out four significant digits from these datasets.
- There is no unambiguous way these authors could have obtained ground truth here. These results are nonsense.

Timeseries Anomaly Detection using Temporal Hierarchical One-Class Network

Assuming that Deep Learning is the Answer

- A large fraction of TSAD papers assume that deep learning is the answer, and their paper reduces to: We will show that this variant of deep learning is better than those seven variants of deep learning².
- However, because of the many reasons discussed above, I think that there is currently *zero* evidence that deep learning is SOTA for TSAD¹.
- Moreover, we should expect deep learning to have difficulties in this setting:
 - Few or no labeled examples
 - Very complex models, with relatively small datasets
 - For time series *classification*, which does have lots of labels, lots of data and lots of constraints, deep learning is only a little bit better than 50-year-old nearest neighbor classification with DTW.
- I am not saying deep learning *could* not work here. But I am willing to say that I do not think *any* current deep learning for TSAD methods can beat simpler decade old approaches. We certainly cannot assume this is the case.

One of the best papers on deep learning TSAD I have read is the recent: *Temporal convolutional autoencoder for unsupervised anomaly detection in time series*.

Usually well written, strong reproducibly, some real insights.

However, at the end of the day, they have to learn or set a dozen parameters to create predictions for datasets like the below (their first dataset of 48 considered)

One of the best papers on deep learning TSAD I have read is the recent: *Temporal convolutional autoencoder for unsupervised anomaly detection in time series*.

Usually well written, strong reproducibly, some actual insights.

However, at the end of the day, they have to learn or set a dozen parameters to create predictions for datasets like the below (their first dataset of 48)

However, a 20-year-old, simple, fast, single-parameter, dozen-lines-of-code method seems to be *at least* competitive. What does the use of deep learning buy for us here?

Example of Deep Learning, but Shallow Thinking

- At least two recent papers did the following
- Use deep learning to look at a PPG signal, and classify the user's behavior into walking/running etc.
- This is a stunning result!
- The result is attributes to various "magical" properties of deep learning.

Example of Deep Learning, but Shallow Thinking II

- But wait a minute..
- If you have the PPG, you can trivially get the heart rate, and the respiration rate (as we have done for decades).
- If you treat it as a simple 2D problem feature, a linear classifier is much better!

Here deep learning is doing nothing magical. It is doing indirectly and expensively, what people have been doing *directly* for decades, and attributing it to the "magic" of deep learning.

Example of Deep Learning, but Shallow Thinking III

- I believe that *most* deep learning for TSAD papers are like the example on the last slide
- They are using complex deep learning to solve a problem that was solvable with much simpler methods decades ago.
- They are attributing their "success" to some vague "magic" of deep learning, not to the fact that the datasets they are working on are trivial!

Late Breaking News

• Two papers make similar observations in a slightly different time series context.

Stabbing William of Ockham in the Heart

Recall the NY Taxi dataset.

Up to the limit of subjectively of labels, it is clear that we can find all the anomalies with simple single-parameter method, for example the Matrix Profile.

Stabbing William of Ockham in the Heart I

Recall the NY Taxi dataset.

Up to the limit of subjectively of labels, it is clear that we can find all the anomalies with simple single-parameter method like time series discords, that has been around for 20 years.

Yet there are dozens of papers that have to learn or set five or more parameters to do the same (or a worse) job on this dataset.

What does that achieve?

framework for end-to-end deep learning-based anomaly detection in transportation networks

Fig. 6. Experiment for the New York City taxi demand dataset. The top plot shows the expected log-likelihood, and the bottom plot shows anomaly segments in red. The blue segments generally do not firmly represent anomalies and need further analysis. In this case, except for August 29, all blue segments refer to national holidays whose patterns are anomalous. The parameters for this experiment are w = 30, k = 6, q = 5, $h_1 = -3.57$, and $h_2 = -4.28$.

Time series anomaly detection from a Markov chain perspective ICMLA 2019

Stabbing William of Ockham in the Heart II

This paper proposes a very complex method "adaptive anomaly detection .. hierarchical edge computing... multiple anomaly detection DNN models with increasing complexity... adaptive model selection scheme ... contextual-bandit problem ... reinforcement learning policy network." [a]. I could not count all the parameters set, but clear more than a dozen. To evaluate it, they use the dataset below and say...

"We manually label a day as abnormal if it is a weekday with low power consumption".

Stabbing William of Ockham in the Heart II

This paper proposes a very complex method "adaptive anomaly detection .. hierarchical edge computing... multiple anomaly detection DNN models with increasing complexity... adaptive model selection scheme ... contextual-bandit problem ... reinforcement learning policy network." [a]. I could not count all the parameters set, but clear more than a dozen. To evaluate it, they use the dataset below and say...

"We manually label a day as abnormal if it is a weekday with low power consumption".

It is a very nicely written paper. But at the end of the day, it is clear that we can find all the anomalies with simple single-parameter method like time series discords, that has been around for 20 years.

[a] Mao V. Ngo, Tie Luo, Hakima Chaouchi, Tony Q. S. Quek: Contextual-Bandit Anomaly Detection for IoT Data in Distributed Hierarchical Edge Computing. ICDCS 2020: 1227-1230

Stabbing William of Ockham in the Heart III

Ockham's razor is perhaps the most fundamental principle in all of science.

In essence, we should prefer the simplest solution to a problem.

However, it is clear that some TSAD papers are proposing solutions that are orders of magnitude more complex than the need to be, given the data they examine.

The solution?

- Test on non-trivial datasets that warrant all this complexity.
- Stop writing this overcomplicated papers.

Not doing anomaly detection, and calling it anomaly detection

Several papers say something like...

- "We manually label a day as abnormal if it is a weekday with low power consumption" [a]
- "A week when any of the first 5 days has low power demands is considered anomalous" [b]
- "we considered anomalies as weekdays that have low level on power consumption" [c]

But think about it. If you can concretely define in a single English sentence what you expect to find in advance, is that really anomaly detection?

Anomaly detection is meant to be *"expect the unexpected"*, but given the above, I could just do similarity search, which is a much easier problem.

Is Deep Learning really useless for Time Series?

- Maybe not: Perhaps no one has figured out how to do properly yet, but one day soon a mind-blowing paper will appear. (And I would be first to champion it)
- Or perhaps that paper is *already* out, but I have foolishly dismissed it, because I find the experiments unconvincing, or because I am just stupid.
- Maybe yes: No one expects deep learning to have an impact on say *sorting numbers*. Maybe time series problems are so simple that they cannot benefit from whatever it is that deep learning does.
- **Maybe yes**: Time series is a little unusual in that we have near perfect distance measure in DTW (which includes Euclidean Distance as a special case). Maybe, given a strong distance measure, nothing else really matters.

Ground Truth Labels are Impossible for Anomaly Detection!

- For some ML problems, we *can* get perfect ground truth, i.e., cats vs dogs
- However, for anomaly detection, we can *never* have perfect ground truth.
- Consider the example below, where is the anomaly?

- Surely it is at the highlighted region?
- No, anyone that has worked in a biomechanical lab has seen this many times, it is the patient turning around at the end of the forceplate apparatus.
- The anomaly is at 16,000, the lack of a heel strike, which *is* unusual.

I have tried and tried to tell folks that if the underlying uncertainty in your labels is larger than any change in relative performance, the change is meaningless
